Increased Risk of Cognitive Impairment in Patients With Diabetes Is Associated With Metformin

EILEEN M. MOORE, PHD1,2 ALASTAIR G. MÅNDER, MBBS2 DAVID AMES, MD1,3 MARK A. KOTOWICZ, MBBS2,4,5 ROSS P. CARNE, MD2,4 HENRY BRODAY, MD6,7 MICHAEL WOODWARD, MD8 KARYN BOUNDY, MD9

KATHRYN A. ELiSS, PHD1,3,10 ASHLEY I. BUSH, PHD11 NOEL G. FAUX, PHD10 RALPH MARTINS, PHD12,13 CASSANDRA SZOEKE, PHD3,14 CHRISTOPHER ROWE, MD15 DAVID A. WATTERS, MBCHM2,4 the AIBL INVESTIGATORS*

OBJECTIVE—To investigate the associations of metformin, serum vitamin B12, calcium supplements, and cognitive impairment in patients with diabetes.

RESEARCH DESIGN AND METHODS—Participants were recruited from the Primary Research in Memory (PRIME) clinics study, the Australian Imaging, Biomarkers and Lifestyle (AIBL) study of aging, and the Barwon region of southeastern Australia. Patients with Alzheimer disease (AD) (n = 480) or mild cognitive impairment (n = 187) and those who were cognitively intact (n = 687) were included; patients with stroke or with neurodegenerative diseases other than AD were excluded. Subgroup analyses were performed for participants who had either type 2 diabetes (n = 104) or impaired glucose tolerance (n = 222).

RESULTS—Participants with diabetes (n = 126) had worse cognitive performance than participants who did not have diabetes (n = 1,228, adjusted odds ratio 1.51 [95% CI 1.03–2.21]). Among participants with diabetes, worse cognitive performance was associated with metformin use (2.23 [1.05–4.75]). After adjusting for age, sex, level of education, history of depression, serum vitamin B12, and metformin use, participants with diabetes who were taking calcium supplements had better cognitive performance (0.41 [0.19–0.92]).

CONCLUSIONS—Metformin use was associated with impaired cognitive performance. Vitamin B12 and calcium supplements may alleviate metformin-induced vitamin B12 deficiency and were associated with better cognitive outcomes. Prospective trials are warranted to assess the beneficial effects of vitamin B12 and calcium use on cognition in older people with diabetes who are taking metformin.

Metformin, vitamin B12, and cognition

2005. Among 242 Australian veterans who had diabetes, metformin was used by 75% in 2005 but decreased to 57% in 2009 (13).

The rate of vitamin B12 deficiency among patients who are taking metformin is reported to approach 30% (14–16). A drug interaction between metformin and the cubilin receptor inhibits the uptake of vitamin B12 from the distal ileum, lowering serum vitamin B12 levels. In a long-term, randomized, placebo-controlled trial, metformin therapy in type 2 diabetes was associated with a 19% reduction in serum vitamin B12 concentrations compared with placebo (17). In a case-control study, Wile and Toth (18) reported that metformin use was associated with reduced vitamin B12 levels and more severe peripheral neuropathy in patients with diabetes.

In a prospective trial, calcium supplements were reported to reverse the drug interaction that causes vitamin B12 deficiency induced by metformin (19). The clinical significance of alleviating metformin-induced vitamin B12 malabsorption by calcium supplementation has not been previously investigated. By correcting vitamin B12 levels in patients with diabetes who use metformin, calcium supplements may help to preserve cognitive function. In addition, neuronal signaling in memory and learning involves a calcium-mediated process, so calcium supplementation may also have a direct effect on the brain. Calcium dysregulation is the subject of one proposed theory for age-related cognitive changes and AD (20). The risks and potential benefits of calcium supplementation on cognition and for alleviating vitamin B12 malabsorption merit further investigation.

The amyloid plaques seen in the brains of patients with AD are formed by 75% in 2005 but decreased to 57% among patients who had diabetes, metformin was reported to reduce the risk of dementia by 24% (hazard ratio 0.76 [95% CI 0.58–0.98]) (25). The purpose of our study was to investigate the associations of metformin, serum vitamin B12 levels, and cognition in a sample of patients with diabetes.

**RESEARCH DESIGN AND METHODS**

**Participants and settings**

Participants were recruited from two prospective studies: the Prospective Research in Memory (PRIME) clinics study and the Australian Imaging, Biomarkers and Lifestyle (AIBL) study of aging. Only data and biochemical measurements pertaining to baseline visits were included in this analysis. The PRIME study recruited 970 participants from 9 sites in Australia, including 3 each in Victoria and New South Wales and 1 each in Queensland, Western Australia, and South Australia. The AIBL study of aging recruited 1,112 participants in Victoria (60%) and Western Australia (40%). The study cohorts and methods of the PRIME and AIBL studies are described elsewhere (26,27).

A further 862 participants who resided in the Barwon region of southeastern Australia between 2001 and 2011 also were recruited through the Cognitive, Dementia and Memory Services clinic at the McKellar Centre, a rehabilitation and aged-care facility. Patients with AD who were seen at a geriatrician’s private practice during the same period also were recruited (n = 933).

**Study design**

Participants in the PRIME study were recruited during routine patient care. AIBL participants volunteered after an advertisement on television in late 2006. The Mini-Mental State Examination (MMSE) was used to assess cognitive ability. Subjects were assessed at scheduled visits during the PRIME and AIBL studies or ad hoc during routine patient care. All participants with serum vitamin B12 measurements taken within 6 months of cognitive assessment were included. Participants without serum measurements taken within 6 months of cognitive assessment were excluded (n = 1,015 were excluded).

The data from records pertaining to subjects who were recruited from more than one source (n = 566) were merged. Of the remaining participants, there were 121 with stroke and 566 with diagnoses other than AD, such as frontotemporal dementia, Parkinson disease, dementia with Lewy bodies, or mixed dementias. Participants with other neurodegenerative diseases were excluded to limit confounders. A further 291 participants were excluded because they had incomplete medical histories; information that was missing included dates of birth, medication use, and comorbid conditions.

A subgroup analysis was performed with participants who had diabetes (n = 104) or impaired glucose tolerance (n = 22). Patients with type 1 diabetes were not specifically excluded, but there were none with serum vitamin B12 measurements taken within 6 months of cognitive assessment.

**Ethical approval**

Institutional review was performed at each study host site. Reviewing committees included the Barwon Health Human Research Ethics Committee (HREC) (Victoria), Austin Health HREC (Victoria), St. Vincent’s Hospital Governance Review Unit (Victoria), Hunter New England HREC (New South Wales), Northern Hospital Network HREC (New South Wales), Northern Sydney Central Coast HREC (New South Wales), Metro North Health Service District HREC (Queensland), South Metropolitan Area Health Service HREC (Western Australia), and The Queen Elizabeth Hospital Ethics of Human Research Committee (South Australia).

**Statistical analyses**

An ordinal logistic regression model was formed with categories of cognitive performance as the response variable and diabetes as a predictor. Categories were ordered by cognitive performance, including “most impaired” (MMSE <18; n = 137), “mildly impaired” (MMSE 18–23; n = 240), “minimally impaired” (MMSE 24–27; n = 293), and “not impaired” (MMSE 28–30; n = 682). The model was adjusted for age, sex, level of education, and depression because these factors were previously reported to affect MMSE testing (28,29).

A subgroup analysis of only patients with diabetes was then performed. The response variable was cognitive performance. Categories were “most impaired” (MMSE <18; n = 39), “mildly impaired” (MMSE 18–23; n = 40), “minimally impaired” (MMSE 24–27; n = 32), and “not impaired” (MMSE 28–30; n = 15). The
effect of metformin on the cognitive performance of patients with diabetes was investigated in this model, which then was adjusted for serum vitamin B12 measurements and use of calcium supplements to investigate any possible interactions. There was insufficient information on use of other antidiabetic drugs, the duration of metformin use, and markers for socioeconomic status, diet, or exercise to investigate these variables.

**RESULTS**—There were 1,354 participants included in this analysis (Fig. 1). Participants were 51–99 years old (mean age ± SD 73.8 ± 8.3 years); females outnumbered males (59.5 vs. 40.5%). Just more than half of the participants (50.4%) scored 28–30 on the MMSE and so were considered not impaired; 21.8% were minimally impaired (MMSE 24–27), 17.7% were mildly impaired (MMSE 18–23), and 10.1% scored less than 18 on the MMSE (most impaired). Participants with diabetes were marginally older than participants without diabetes (75.5 vs. 73.6 years; \( P = 0.013 \)). The number of males was proportionally larger among participants with diabetes (46.8 vs. 39.9%), but this difference was not statistically significant. Prevalence of depression was similar between participants with diabetes and those without diabetes (31.7 vs. 27.3%; \( P = 1.000 \)). The proportion of participants with a tertiary level of education was higher among participants without diabetes than participants with diabetes (39.3 vs. 22.2%; \( P < 0.001 \)). The number of participants who scored below 28 on the MMSE was proportionally higher among participants with diabetes than those without diabetes (69.0 vs. 47.6%; \( P = 1.000 \)).

After adjusting for age, sex, education, and depression, participants with type 2 diabetes had worse cognitive performance than participants without diabetes (adjusted OR 1.51 [95% CI 1.03–2.21]). Cognitive performance was better in younger participants, those without depression, and those with a higher level of education. The adjusted ORs for each predictor are shown in Table 1.

Among participants with diabetes, cognitive performance was worse in patients who were taking metformin (adjusted OR 2.23 [95% CI 1.05–4.75]). MMSE scores were lower in participants with diabetes who used metformin (mean score ± SD 22.8 ± 5.5) than in those who did not use metformin (24.7 ± 4.4). Participants with diabetes who had vitamin B12 levels <250 pmol/L also had worse cognitive performance (2.29 [1.12–4.66]). MMSE scores were lower among those with serum vitamin B12 <250 pmol/L (22.9 ± 4.7) than those with higher levels (25.0 ± 4.7).

Each 1-year increase in age was associated with an 8% increased risk of impaired cognitive performance (OR 1.08 [95% CI 1.03–1.13]). A secondary or...
Model adjusters

**CONCLUSIONS**—In our series, patients with diabetes who were taking metformin had worse cognitive performance than participants who were not taking metformin. Our observations agree with those previously reported by Imfeld and colleagues (22), in particular that patients who are taking metformin may have an increased risk for cognitive impairment. This association was weakened after adjusting for serum vitamin B₁₂ levels; thus any effect metformin has on cognitive performance may be at least partially mediated by altering serum vitamin B₁₂ levels.

Alternatively, patients who are prescribed metformin may have worse glycemic control or diabetes-related complications than patients with diabetes who are not prescribed metformin, so there remains the potential for confounding, despite restricting the analysis to only patients with diabetes. However, because metformin is a first-line pharmacotherapy for the treatment of type 2 diabetes, this would seem unlikely (30).

There was insufficient information regarding the duration of metformin use, the severity of diabetes (e.g., HbA₁c levels), duration of diabetes, or use of other antidiabetic drugs to enable us to investigate these effects in our study, particularly because these findings were based on a small sample. We recommend a larger study to examine the effect of dose and duration of metformin use, and the effects of other antidiabetic agents using a battery of cognitive assessments and following participants over a number of years.

Calcium supplements have previously been reported to reverse vitamin B₁₂ deficiency induced by metformin. In this study, patients with diabetes who used calcium supplements were less likely to be cognitively impaired. However, calcium supplements have been reported to be associated with an increased risk for myocardial infarction in postmenopausal women and in patients with chronic kidney disease (31–34). In contrast, a recent meta-analysis indicates that supplementation with both vitamin D and calcium is associated with a reduction in mortality compared with vitamin D supplementation alone (35). Because this population already has increased cardiovascular risk (36), the safety of calcium supplementation in patients with diabetes treated with metformin would need to be established before such interventions could be recommended.

Patients with diabetes are at an increased risk for AD (10). In diabetes, amylin aggregation destroys the β-cells of the pancreas (37). By the same mechanism, a protein misfolding disorder may be related to aggregation of amyloid plaques. Metformin is a widely prescribed first-line monotherapy for type 2 diabetes but is associated with vitamin B₁₂ deficiency and peripheral neuropathy. A case-control study of more than 14,000 patients reported that long-term metformin use was associated with an increased risk for AD in those ≥65 years old (22). Metformin at pharmacological doses was reported to increase the expression of β-secretase in cell culture; this may be a possible disease mechanism (21). Alternatively, metformin also impairs absorption of vitamin B₁₂ via a drug interaction that occurs at the distal ileum. Low serum vitamin B₁₂ levels are associated with AD and other neurodegenerative diseases (38).

Cognitive performance of patients with diabetes was measured using the MMSE. The MMSE may be inadequate for detecting differences between higher functioning adults (39). The MMSE is sensitive to age, depression, and level of education, so all models were adjusted for these factors. Most of our subjects were

All models were adjusted for age, sex, reported history of depression, and level of education. Values obtained in the model that also was adjusted for serum vitamin B₁₂ levels are italicized. *Reference levels for categories were female sex, no reported history of depression, and having attained a primary level of education only (up to 6 years of schooling).†Serum vitamin B₁₂ status was defined as low (serum levels <250 pmol/L) or normal (serum levels >250 pmol/L).‡Impaired glucose tolerance was by self-report or review of patient’s medical history. §Categories for level of education were tertiary (>13 years of schooling), secondary (6–13 years of schooling), and primary (<6 years of schooling).
assessed during routine clinical care by clinicians who use the MMSE as part of their standard assessment. In Australia, documentation of cognitive impairment using an MMSE score and improvement while receiving therapy is required to obtain subsidized antidementia therapies (40). More comprehensive assessment tools may be preferable for use in future investigations of cognitive impairment in at-risk populations such as those we have studied.

Increased monitoring of cognitive ability in patients with diabetes who use metformin is warranted, particularly among older adults (aged older than 50 years). Vitamin B12 supplements are inexpensive and may improve the cognitive outcomes of patients with diabetes. Adequately powered, prospective, controlled trials are warranted to investigate further the association between diabetes, cognitive decline, and the effect of metformin therapy, as well as the possible amelioration using vitamin B12 and/or calcium supplementation.

Acknowledgments—The PRIME study was funded by Janssen Australia. This study received support from the National Health and Medical Research Council via the Dementia Collaborative Research Centres program (DCRC2). The AIBL study currently receives funding from the Science Industry Endowment fund.

Pfizer International contributed financial support to assist with analysis of blood samples and to further the AIBL research program. Core funding for the AIBL study was provided by the Commonwealth Scientific and Industrial Research Organisation (CSIRO), which was supplemented by in-kind contributions from the study partners: The University of Melbourne, Neurosciences Australia Ltd., Edith Cowan University, Mental Health Research Institute, Alzheimer’s Australia, National Ageing Research Institute, Austin Health, University of Western Australia, CoeState Ltd., Macquarie University, Hollywood Private Hospital, and Sir Charles Gardner Hospital.
